11 Abstract

12 Animals are colonized by bacteria, and in many cases partners have co-evolved to perform mutually
13 beneficial functions. An exciting and ongoing legacy of the past decade has been an expansion of
14 technology to enable study of natural associations *in situ/in vivo*. As a result, more symbioses are
15 being examined, and additional details are being revealed for well-studied systems with a focus on
16 the interactions between partners in the native context. With this framing, we review recent literature
17 from the *Vibrio fischeri*-*Euprymna scolopes* symbiosis and focus on key studies that have had an
18 impact on understanding bacteria-animal interactions broadly. This is not intended to be a
19 comprehensive review of the system, but rather to focus on [particular studies that have excelled at](#)
20 [moving from pattern to process in facilitating an understanding of](#) the molecular basis to intriguing
21 observations in the field of host-microbe interactions. In this review we discuss the following topics:
22 processes regulating strain and species specificity; bacterial signaling to host morphogenesis;
23 multiple roles for nitric oxide; flagellar motility and chemotaxis; and efforts to understand
24 unannotated and poorly annotated genes. Overall these studies demonstrate how functional
25 approaches *in vivo* in a tractable system have provided valuable insight into general principles of
26 microbe-host interactions.

27 1 Introduction

28 Studies of human, animal, and plant microbiomes have been advanced by novel culture-independent
29 approaches and technological advancements in DNA sequencing. In recent years a prominent role for
30 microbial communities of the gut, skin, and other organs has emerged as modulators of human health
31 (Human Microbiome Project Consortium, 2012). These studies followed from influential animal
32 studies in systems that are yielding critical insight into microbiome assembly, stability,
33 communication, and evolution (McFall-Ngai et al., 2013; Ruby, 2008). The focus of this review is to
34 examine one model system, the *Vibrio fischeri*-*Euprymna scolopes* symbiosis, and how key findings
35 in that system have enabled an increasingly higher resolution of the processes and principles that
36 underlie microbe-host communication.

When Hawaiian bobtail squid hatch from their eggs, they are exposed to a million bacteria in each milliliter of seawater. Although *V. fischeri* make up less than 1 in 5,000 of these planktonic, environmental bacteria, the “light organ” of the hatchling squid becomes colonized exclusively with *V. fischeri* (Mandel, 2010; Ruby and Lee, 1998). The microbe-host specificity relies on a series of reciprocal communications between the partners, many of which are detailed in the sections below. Over the course of 48 hours the bacteria establish a mature colonization in epithelium-lined crypts of the squid light organ, and, at high cell density, produce light as a result of quorum-sensing. The bacterial bioluminescence is reflected by host tissue to camouflage the shadow or silhouette that the nocturnal-foraging squid would cast in the moonlight, thus protecting the host in a process termed counter-illumination (Jones and Nishiguchi, 2004; Ruby and McFall-Ngai, 1992). Initiation of colonization occurs in newly-hatched squid, seeding an individual host’s crypts for its lifetime. The bacteria produce light at night, then at dawn approximately 90-95% of the symbiotic population is expelled into the seawater (Boettcher et al., 1996; Lee and Ruby, 1994; Nyholm and McFall-Ngai, 1998). The remaining cells grow up during the day, produce light at night, and a diel cycle of growth, light production, and expulsion proceeds for the lifetime of the animal (Wier et al., 2010). Host cellular changes accompany this cycle, e.g. a daily reshaping of the epithelial brush border against which the bacteria reside during the final two hours prior to the daily expulsion (Wier et al., 2010).

Deleted: .

As an environmentally-transmitted symbiosis, the *Vibrio*-squid model has a number of valuable characteristics that have served it well as a study system for identifying molecular mechanisms. First, the binary system (two partners) is naturally reduced. Second, both partners can be raised separately and then introduced for experimentation. Third, *V. fischeri* is genetically tractable, and unbiased mutagenesis as well as precise genetic alterations can be introduced with relative ease. Fourth, the bacteria colonize the host light organ directly under the semi-transparent mantle and funnel; this permits imaging of the site of infection and direct analysis of bacterial behaviors and host responses. Fifth, synchronous colonization of hatchlings has permitted developmental staging of the colonization process. For most of the processes described below, many of these benefits were important in the advances described.

2 From pattern to process in the *Vibrio*-squid symbiosis

In each section below, we highlight key discoveries in the *Vibrio*-squid symbiosis with a specific focus on how this model system has revealed molecular processes that underlie mutually beneficial phenotypes.

2.1 Just the two of us

E. scolopes squid light organs are colonized only by *V. fischeri*, and this exclusivity has guided substantial inquiry and discovery in the system. This pattern was first explored by McFall-Ngai and Ruby (McFall-Ngai and Ruby, 1991) and extended in subsequent works (Mandel et al., 2009; Ruby and Lee, 1998). The ability to image the live animal during colonization enabled the discovery of *V. fischeri* aggregating in close proximity to the ciliated epithelial fields of the light organ (Nyholm et al., 2000). Nyholm discovered that a narrow distance between the green fluorescent protein-expressing bacteria and the squid epithelial tissue was the result of host-produced mucus, which included *N*-acetylneuraminic acid and *N*-acetylgalactosamine. Recent work has demonstrated that *V. fischeri* bind to cilia within this mucus field (Altura et al., 2013). Whereas many bacteria can bind in host mucus, only specific strains and species exhibit a competitive dominance over non-colonizing isolates, and only (some) *V. fischeri* strains proceed to fully initiate colonization (Mandel et al., 2009; Nyholm and McFall-Ngai, 2003; Nyholm et al., 2000).

82 Around this same time, the genetic basis for bacterial aggregation was being discovered and
 83 characterized in the laboratory of Karen Visick. A forward genetic screen for colonization factors
 84 first identified an orphan histidine kinase, RscS (regulator of symbiotic colonization-sensor), but
 85 without a phenotype or target it was difficult to know how this factor connected to the colonization
 86 process (Visick and Skoufos, 2001). The same screen identified an eighteen gene locus that encoded
 87 regulatory proteins, glycosyltransferases, and other factors involved in exopolysaccharide production
 88 and export. Mutations in this region, the *syp* locus (symbiosis polysaccharide), conferred dramatic
 89 colonization defects in the animal as well as defects in biofilm formation in culture (Yip et al., 2005).
 90 A connection between these earlier studies was discovered when it was shown that RscS regulates
 91 expression of the *syp* locus (Yip et al., 2006). Overexpression of RscS provided a valuable tool in
 92 which bacterial colony formation took on a wrinkled or rugose colony morphology that is typical of
 93 biofilm formation (Yip et al., 2006). Phenotypes of *rscS* and *syp* alleles in colony-based biofilm
 94 assays map closely to their phenotypes during squid colonization, providing a valuable experimental
 95 tool for discovery and characterization of biofilm regulation. Further work has identified multiple
 96 layers of regulation, including a negative regulatory pathway that includes SypE and SypA, putative
 97 matrix proteins that integrate with the polysaccharide matrix, and a unique phosphorelay pathway
 98 (Morris and Visick, 2013; Norsworthy and Visick, 2015; Ray et al., 2015; Visick, 2009).

99 The genetic approaches described above (and in most studies in this review) were conducted in strain
 100 ES114, a squid isolate from Kaneohe Bay, Hawaii, that is used widely as a canonical squid symbiont.
 101 In addition to the biofilm regulatory pathway, a number of approaches including forward and reverse
 102 genetics studies had identified factors in strain ES114 that were important for squid colonization
 103 (Stabb and Visick, 2013). However, only some *V. fischeri* strains can colonize squid. Therefore, to
 104 examine the genetic basis for this host colonization specificity, Mandel and colleagues conducted a
 105 comparative genomic analysis of strains ES114 and MJ11, the latter being a fish symbiont that does
 106 not colonize squid robustly (Mandel et al., 2009). The study determined that 91 % of ES114 genes
 107 were almost identical between the squid and fish symbiont, but that approximately 400 genes in each
 108 strain were unique. Analysis of these factors revealed that the squid biofilm regulator, RscS, was
 109 encoded in the squid symbiont but not in the fish symbiont. The known RscS target genes, *sypA*,
 110 *through sypR* were encoded in both genomes and fairly conserved (>85 % amino acid identity). It
 111 was known previously that ES114 mutants that lacked RscS were unable to productively colonize the
 112 squid (Visick and Skoufos, 2001). Therefore, the study asked whether the absence of the regulator
 113 could explain the differential colonization phenotype. Introduction of RscS into strain MJ11 was
 114 sufficient to allow it to colonize the squid host. Phylogenetic analyses supported a model in which
 115 MJ11 was part of an ancestral group of *V. fischeri* that lacked *rscS*, and that this gene was acquired
 116 coincident with colonization of squid in the North Pacific Ocean (i.e., Japan and Hawaii).

Deleted: , *sypB*, ...,

117 The idea that a single gene was sufficient to shift the animal hosts available to a bacterium was
 118 extreme but consistent with emerging literature that individual loci could impact microbe-host
 119 specificity. Work in entomopathogenic nematodes showed that symbiotic *Xenorhabdus nematophila*
 120 requires the three-gene *niABC* locus for colonization, and that expression of these factors in a
 121 heterologous symbiont is sufficient to enable colonization of *Steinernema carpocapsae*, the worm
 122 host that otherwise is specific for *X. nematophila* (Cowles and Goodrich-Blair, 2008). Small genetic
 123 changes in *Yersinia pestis* have been key to its ability to colonize new niches, including single gene
 124 acquisitions and even inactivation of a gene already present (Sun et al., 2008, 2014; Zimble et al.,
 125 2015). In the human gut microbiome there are examples in which single gene changes have been
 126 critical; e.g., in *Bacteroides fragilis*, polysaccharide A (PSA) confers a key immunomodulatory
 127 benefit that cannot be obtained from the other seven capsular polysaccharides produced (Mazmanian
 128 et al., 2008).

Deleted: an

Studies on host colonization specificity in general, and biofilm formation in particular, have highlighted many of the strengths of the squid model. Imaging *in situ* was key to the initial discovery of the aggregates, forward genetics identified core exopolysaccharide synthetic and regulatory components, comparative genomics revealed the role of this pathway in the evolution and specificity of the association, and high-throughput genetic approaches are identifying additional levels of regulation. Additionally, this work highlights the value of model systems of beneficial bacteria, including *Vibrio* and *Xenorhabdus* models, to identify mechanistic details that resonate in beneficial and pathogenic colonization models.

2.2 The **Code Word** is TCT

Deleted: Codeword

E. scolopes squid provide a particularly dramatic example of a role for bacteria influencing a specific host developmental process. Development of the host tissue proceeds on different trajectories depending on whether the specific symbiont *V. fischeri* is present. Only once the symbiont has colonized, the ciliated appendages of the host light organ undergo apoptosis, hemocyte infiltration, and tissue regression during the subsequent five days (Koropatnick et al., 2004; McFall-Ngai and Ruby, 1991; Montgomery and McFall-Ngai, 1994). The host morphogenesis is striking, with appendages that begin as outstretched mucus factories to recruit colonizing bacteria being reduced to small stumps (Montgomery and McFall-Ngai, 1994). As a result, it seems that initiation of the symbiosis is restricted to the first few days of the animal's life while the appendages are present and secreting mucus.

How does the host know that the bacteria are inside to appropriately time the regression? It turns out that *V. fischeri* sheds envelope components that are received by receptors on the host. In particular, the bacterial peptidoglycan fragment, tracheal cytotoxin (TCT)—previously shown to induce a damaging apoptosis in ciliated epithelia upon release from *Bordetella pertussis*—was identified to perform a similar function in *V. fischeri*, but this time with a resulting beneficial outcome (Koropatnick et al., 2004). To recapitulate the apoptosis phenotype observed when intact *V. fischeri* are presented to the host, in the absence of the bacteria both the Lipid A portion of lipopolysaccharide (LPS) and TCT are required. The cell death from these compounds, in conjunction with hemocyte trafficking that is also induced from TCT, results in the regression phenotype. Previously these compounds had only pathogenic associations, but this work underscored a remarkable conservation to the cell biology of microbial-host interactions, emphasizing the context of the interaction to understand the fitness effects on the partners involved (Koropatnick et al., 2004).

Once the bacteria announce their arrival, how does the host speak back? In addition to regression of the appendages that recruit the bacteria, there are additional mechanisms by which the host receives and likely modulates the bacterial signal. Host nitric oxide production, described in more detail below, is diminished as a result of bacterial signaling (synergistically with LPS) (Altura et al., 2011). The host produces a peptidoglycan recognition protein, EsPGRP2, which is secreted into the bacterial-containing crypts and has the ability to degrade TCT (Troll et al., 2010). Additionally, there are data to suggest that host alkaline phosphatase, EsAP, modifies Lipid A after the initial signaling (Rader et al., 2012). In each case the host response is to diminish the potency of the bacterial products, but only after they have exerted their influence on host development.

Deleted: crypts

Deleted: bacteria

This work in *V. fischeri* was influenced by studies in invertebrate systems that demonstrated host development in response to symbiont colonization and in vertebrates that showed general responses to consortia (reviewed in Montgomery and McFall-Ngai, 1994, and more recently in McFall-Ngai, 2014), and itself has influenced a field in which bacterial products play important roles in animal

Deleted:),

development. An early mammalian example by Hooper and Gordon demonstrated that in response to colonization by gut *Bacteroidetes* such as *Bacteroides thetaiotaomicron*, terminal tissue differentiation (e.g., fucosylation) is dependent on the presence of the symbiotic bacteria (Hooper and Gordon, 2001). There now exist many examples of bacteria directing specific host development. Recent exciting examples include *Algoriphagus machipongonensis* sulfonolipid signaling for multicellular rosette development in the choanoflagellate *Salpingoeca rosetta*, and *Pseudoalteromonas luteoviolacea* phage tail-like structures that stimulate tubeworm metamorphosis (Alegado et al., 2012; Shikuma et al., 2014).

2.3 NO way in

There is a long history of the study of nitric oxide (NO) in eukaryotes, and this small diffusible molecule has been implicated in many different cellular processes including signaling and innate immunity (Fang, 2004). Although the roles for NO in eukaryotic physiology and defense against pathogens were discovered many years ago, the study of this compound in the *Vibrio*-squid system and other symbioses (Damiani et al., 2016) has revealed that NO also influences the establishment and maintenance of mutualistic microbe-host relationships as both a signal and a specificity determinant (Wang and Ruby, 2011).

Davidson, et al. (Davidson et al., 2004) first demonstrated that NO is produced in squid host tissue through the activity of nitric oxide synthase (NOS), and this activity was attenuated after successful colonization by *V. fischeri*. Using staining and immunocytochemistry, NOS and NO were found located in the epithelium of the light organ, as well as in vesicles within mucus shed from these cells. It is within this mucus that the bacterial cells aggregate prior to entering the light organ. Normally, *V. fischeri* aggregate in the mucus, colonize the host, and after successful colonization NOS activity and NO production are attenuated. Treatment of the animals with an NO-scavenging compound to diminish NO levels allowed large aggregates of non-symbiotic vibrios to form, but these bacteria did not successfully initiate colonization. (Davidson et al., 2004) The results suggested that NO acts as a specificity determinant, helping to limit aggregation of non-symbiotic vibrios and select for symbiotically competent *V. fischeri* from the mixed microbial population found in seawater.

If NO plays a role in specificity, then how do colonizing *V. fischeri* sense and respond to the host-produced NO to successfully establish the partnership? Using genetic approaches it was demonstrated that a strain lacking the NO-detoxifying enzyme flavohemoglobin (Hmp) displayed a colonization deficiency (Poole and Hughes, 2000; Wang et al., 2010b). Expression of *hmp* is regulated by the NO-responsive negative regulator NsrR (Rodionov et al., 2005; Tucker et al., 2010). However, NsrR is not the only important NO-sensing regulator in *V. fischeri*. H-NOX, a heme NO/oxygen-binding protein, also plays a role in symbiotically relevant NO-responsive regulation of genes in *V. fischeri* (Wang et al., 2010a). Although H-NOX-like proteins are widely distributed in bacteria, this was the first report describing bacterial H-NOX function. Interestingly, it appears that one role for H-NOX in *V. fischeri* is to sense NO and correspondingly suppress bacterial hemin uptake during the early stages of host colonization. The authors predicted that early repression of iron uptake would protect the cells from the potentially harmful effects of Fenton chemistry when they are exposed to host-generated oxidants (Davidson et al., 2004; Graf and Ruby, 2000; Wang et al., 2010a). Consistent with this model, hemin uptake genes in *V. fischeri* were shown to be induced during the later stages of symbiotic colonization, and deletion of these genes negatively impacted colonization (Septer et al., 2011). Together, these studies support a model whereby host NO stimulates repression of hemin uptake genes; once bacterial colonization leads to an attenuation of host oxidant production, then hemin uptake genes are derepressed to support growth in the iron-

Deleted: was

225 limited light organ environment. Therefore, the ability to sense and detoxify NO is important for
 226 symbiotic specificity, and NO acts as a temporal signal to modulate bacterial gene expression and
 227 promote successful colonization.

228 Although these studies have led to a better understanding of the role of a few key proteins and
 229 regulators in the response of *V. fischeri* to NO and the initial stages of the symbiosis, there is much
 230 yet to be learned about the global effects of NO on *V. fischeri* gene expression and metabolism, how
 231 this molecule acts as a specificity determinant, and whether there is a role for NO in the mature
 232 symbiosis. For example, the work of Wier et al. has suggested that NO may play a role in the daily
 233 symbiotic rhythm in the adult animal (Wier et al., 2010). Their data predicted that nitrate/nitrite
 234 respiration is used by the bacterial symbionts throughout the daylight hours. Similarly to *Escherichia*
 235 *coli* (Vine and Cole, 2011), it is predicted that NO is produced by *V. fischeri* during respiration of
 236 nitrate/nitrite in laboratory culture. Endogenously-produced NO could induce alternative respiratory
 237 pathways that likely influence the physiology and metabolism of the bacterium (Dunn et al., 2010).
 238 Together these separate lines of evidence suggest that NO may play a role beyond signaling and
 239 selection in the initiation of the symbiotic relationship. In the future it will be exciting to combine
 240 studies of NO and the bacterial NO response with the more recently developed ability to rear squid to
 241 adulthood (Koch et al., 2013; see section below on light production).

242 The value of further studies of NO in the *Vibrio*-squid system lie not only in providing important
 243 information about the role of this molecule in beneficial host-microbe interactions, but also for
 244 comparative studies to host-pathogen responses. Our current understanding supports a view that NO
 245 is being produced by the host and sensed by the bacteria in similar ways in many of the studied host-
 246 ~~microbe~~ interactions, whether the outcome of the relationship is beneficial or detrimental (Fang,
 247 2004; Wang and Ruby, 2011). The prevalence of NO in host tissues colonized by bacteria suggests
 248 that a better understanding of the role of NO in symbiosis may have wide-reaching consequences for
 249 microbes at the interface of health and disease.

250 2.4 Swimming against the flow

251 In the mucus field that serves as the entry point for bacteria heading into the host, colonizing bacteria
 252 enter at one of three pores on either side of the bilaterally symmetrical light organ. Mucus is shed
 253 from the pores of the host at the same time that *V. fischeri* aggregates in that mucus. The bacteria
 254 proceed to migrate toward the pores, and each aggregate swims into a pore to colonize the ducts and
 255 crypts of the host. How do colonizing bacteria travel against this powerful flow? A key role for
 256 flagellar motility was identified over twenty years ago (Ruby and Asato, 1993). In that work Ruby
 257 and Asato confirmed that planktonic *V. fischeri* were motile due to a polar tuft of sheathed flagella.
 258 However, by 24 hours-post-inoculation most cells in the light organ crypts were non-flagellated.
 259 Upon expulsion of bacteria from the host, the bacteria regrow their flagella in 45-60 min even in
 260 nutrient-deplete seawater (Ruby and Asato, 1993). Therefore, the bacterial life cycle alternates
 261 between a motile planktonic lifestyle and a non-flagellated crypt-colonized state.

262 Significant details have since been elucidated about the molecular mechanisms that control flagellar
 263 development in *V. fischeri*, which in turn has solidified the importance of swimming motility for
 264 squid colonization. Random transposon mutagenesis provided evidence that nonmotile mutants could
 265 not colonize (Graf et al., 1994), and reverse genetics revealed that mutants defective for flagellar
 266 motility or chemotaxis did not establish productive colonization with the squid host (DeLoney-
 267 Marino and Visick, 2012; Millikan and Ruby, 2003, 2004). Together these studies established a
 268 model of a hierarchy of flagellar gene expression in *V. fischeri* controlled by the σ_{54} -dependent

272 regulator FlrA. There is evidence for regulation by quorum sensing and magnesium, and other
273 sensory inputs are likely (Cao et al., 2012; O'Shea et al., 2005).

Deleted: by

274 Bacterial flagellar motility often occurs in a directed fashion in which rotation of the flagellar bundle
275 results in net movement toward preferred nutrient sources. Given the above information that
276 chemotaxis was required for colonization, it seemed likely that the bacteria were swimming toward a
277 host compound. The first evidence for chitin oligosaccharides as the specific attractant was obtained
278 when addition of exogenous chitobiose, the *N*-acetylglucosamine dimer, blocked colonization,
279 whereas the monomer did not have such an effect (Mandel et al., 2012). Given that *N*-
280 acetylglucosamine is abundant on eukaryotic cell surfaces, yet chitin and its breakdown
281 oligosaccharides are more specialized in their localization, it seemed possible that oligosaccharides
282 may be a specific cue to direct entry into the host crypts. Mutants defective for chemotaxis remained
283 at the outer face of the light organ pore, the same stage at which wild-type *V. fischeri* arrested their
284 symbiotic development in the presence of added chitin oligosaccharides (Mandel et al., 2012). These
285 results strongly suggested that host chitin served as a signal for the bacteria to enter the pore. Direct
286 imaging revealed the presence of insoluble chitin bound to hemocytes within the host (Heath-
287 Heckman and McFall-Ngai, 2011; Mandel et al., 2012), which may be released through the action of
288 a host endochitinase (Kremer et al., 2013). Together, this illustrates a specific colonization
289 checkpoint that is regulated by both host and symbiont factors.

290 Work on bacterial motility at the host interface has provided a valuable toolset to probe mechanisms
291 of symbiosis and reveal novel signaling pathways. Many bacterial strains have dozens of genes that
292 encode chemotactic sensory proteins, the methyl-accepting chemotaxis proteins (MCPs). The set of
293 43 MCPs in *V. fischeri* is typical in this regard, and despite difficulties in studying a large protein
294 family, functions have now been assigned to three of these proteins. VfcA is the major amino acid
295 chemoreceptor, and VfcB and VfcB2 are fatty acid chemoreceptors (Brennan et al., 2013;
296 Nikolakakis et al., 2016). In addition to providing information directly about colonization, these tools
297 provided insight into the role of LPS during colonization and for the evolution and the generation of
298 torque at the flagellar motor (Beeby et al., 2016; Post et al., 2012). Furthermore, recent work suggests
299 that the rotation of the flagella—which is enclosed in an LPS sheath—stimulates outer membrane
300 vesicle release and triggers the host immune response by promoting LPS release (Aschtgen et al.,
301 2016; Brennan et al., 2014).

302 Satisfying answers to some of these questions are beginning to be addressed, including a role for cilia
303 in modulating adhesion, as well as chemotaxis toward host-produced and host-cleaved chitin
304 modulating a key developmental checkpoint. Still, important questions remain that suggest novel and
305 interesting biology to be revealed through the symbiosis. Open questions include how bacteria transit
306 through the mucus in a flagellar-independent manner; the molecular basis of chitin oligosaccharide
307 sensing in the symbiont; and the processes that regulate the developmental switch between the
308 aflagellate state in the host versus the swimming state in seawater.

309 2.5 Light up my life

310 An important aspect to mutualistic symbioses is the selection of appropriate and cooperative partners.
311 In both the rhizobium-leguminous plant (Kiers et al., 2003) and *Vibrio*-squid symbioses the microbial
312 partners provide costly services to their hosts (nitrogen fixation and light production, respectively). In
313 theory, these relationships could be exploited by symbionts that are less cooperative (i.e. “cheaters”)
314 (Ghoul et al., 2014). However, it is rare to find bacterial symbionts associated with the hosts that do
315 not provide these services. Therefore, the *Vibrio*-squid mutualism provides an excellent model

317 system for studying cooperative partner stability, and studies to date indicate that bacterial light
318 production is required for bacterial cells to persist in the light organ.

319 *V. fischeri* is known to produce light in the squid host, and a key study demonstrated a role for
320 luciferase, the enzyme that produces light, in bacterial symbiotic persistence (Visick et al., 2000).
321 Mutants with defective luminescence structural genes or luminescence regulatory genes colonized
322 juvenile squid to the same levels as wild type in the first 24 hours. However, by 48 hours there was a
323 three- to four-fold reduction in colonization by the dark mutants relative to wild-type controls. In
324 squid co-colonized with both a luminescence mutant and wild type, levels of the mutant strains
325 similarly decreased, indicating that light-producing wild-type cells in the light organ could not
326 complement the colonization defect of the light-deficient cells. These results suggested that the
327 ability of individual bacteria to produce light was important for persistence in the light organ, and
328 that somehow non-luminescent cells are selected against during development of the symbiosis.

329 Interestingly, the light-deficient strains have a specific effect on host development. Although
330 colonization by a luminescence mutant still triggered apoptosis-related developmental changes in the
331 ciliated surface of the light organ, colonization of the tissue by these strains no longer increased cell
332 swelling of the epithelial cells lining the light organ crypt spaces. Therefore, light production
333 appeared to play a specific role in host developmental pathways. Notably, this was the first report of
334 *V. fischeri* genes required for induction of bacterial-triggered differentiation of host tissue (Visick et
335 al., 2000).

336 It was later discovered that the antibiotic markers and method for constructing the early luminescence
337 mutants (Visick et al., 2000) resulted in colonization attenuation and pleiotropic effects. In a later
338 study, newly developed genetic tools were used to construct luminescence mutants that were not
339 negatively affected in growth and colonization (Bose et al., 2008). Using these strains, the early
340 results were confirmed demonstrating that the strain lacking the luminescence structural genes
341 displayed a four-fold reduction in colonization as compared to wild type at 48 hours-post-inoculation.

342 Previous studies suggested that maintenance of the symbiosis over the life of the animal requires a
343 maturation process of several weeks (Montgomery and McFall-Ngai, 1998), leaving the question of
344 how production of light influences symbiosis maturation beyond 72 hours. A major breakthrough for
345 the field came with the development of protocols for simplified rearing of newly-hatched juvenile
346 squid through and beyond the maturation process. These methods allowed investigation of how
347 bacterial-produced light affects the development of the symbiosis over four weeks (Koch et al.,
348 2013). In these studies, the levels of the luminescence-deficient mutant associated with the squid
349 light organ continued to diminish over time, to the minimum level of detection after 28 days. Similar
350 results were observed in squid colonized with mixed inocula containing both wild type and the
351 luminescence mutant, where after 15 days the mutant was barely detected. Therefore the persistence
352 defect observed during early colonization becomes more pronounced as the symbiosis matures, with
353 eventual loss (or near loss) of non-luminescent strains in a matter of weeks.

354 Luminescence regulation is one of the hallmarks of the *V. fischeri*-squid symbiosis and has been
355 studied intensively, yet there are still exciting open questions. First, how are the dark mutants
356 removed from the population even in the midst of neighboring bright populations? A clue comes
357 from studies testing the influence of a previous colonization event on recolonization (Koch et al.,
358 2013). Juvenile animals were colonized with either wild type or a luminescence mutant. After 1-5
359 days, the animals were treated with antibiotics to clear bacteria from the light organ and then exposed
360 again to wild-type *V. fischeri* to test whether light production is a “signal” to the host that influences

361 symbiotic maturation. Animals treated with antibiotics after one day were readily recolonized,
 362 regardless of the strain that initially colonized. However, after five days, wild-type *V. fischeri*
 363 induced a refractory state in the animal that prevented recolonization. In contrast, in animals initially
 364 colonized by a luminescence mutant, greater than 80% of the animals were recolonized by wild type.
 365 These results support the idea that the host is detecting light production by bacterial cells and/or is
 366 altering physiological conditions to sanction the non-luminescent strains. In addition, the host
 367 apparently is able to “eject” an inappropriate light deficient strain, ~~directly or indirectly~~ while
 368 allowing future recolonization by a symbiotically appropriate light-producing strain. The exact
 369 mechanisms by which the detection, sanctioning, and/or ejection occurs remain to be described. The
 370 host does have the capacity to detect light but it is unknown whether this capacity is connected to
 371 symbiont selection (Tong et al., 2009).

Deleted: ,

372 A second interesting question relates to how bacterial light production is matched to the moonlight in
 373 such an exquisite fashion. The squid contains elaborate tissues to physically reflect and modulate
 374 bacterial light production (Crookes et al., 2004). This physical response could be triggered through
 375 the activity of products of host cryptochrome and eye-specification genes; the expression of these
 376 genes appears to be influenced by the light produced by *V. fischeri* (Heath-Heckman et al., 2013;
 377 Peyer et al., 2014). The physical reflection and modulation of bacterial luminescence is also
 378 coordinated with a molecular signaling response. For example, host epithelial cells swell in response
 379 to light-producing strains but not dark mutants (Visick et al., 2000). This swelling could release
 380 chemical cues into the light organ environment. Recent evidence indicates that bacterial
 381 luminescence in the light organ is controlled not only through quorum sensing, but also through
 382 response to environmental signaling (Septer and Stabb, 2012). These results suggest there is complex
 383 chemical and physical control of light production in the symbiosis. Bacterial luminescence is a
 384 particularly intriguing and engaging aspect of the *Vibrio*-squid symbiosis, and it is clear that there are
 385 abundant questions remaining to be addressed as to how the interaction with the host and the
 386 environment lead to specific phenotypic output in the host.

387 2.6 Nice to meet you... now what is it you do?

388 The *Vibrio*-squid symbiosis has provided a useful framework for identifying the function of bacterial
 389 genes and studying novel genes *in vivo*. Due to the wealth of genetic tools that have been developed
 390 for *V. fischeri* and the ability to access the host interface with direct imaging, it is possible to test the
 391 effects of gene loss in the real-world environment of the host. Two examples discussed below are
 392 using the *Vibrio*-squid system to broaden understanding of gene function for alternative oxidase
 393 (AOX) and for discovering the role of the biofilm inhibitor Bink.

394 AOX is a terminal respiratory oxidase that is ubiquitous in plants, and is unusual because its activity
 395 is not directly linked to generation of the proton motive force (Vanlerberghe and McIntosh, 1997).
 396 The study of the function of AOX in plants is an active area of research, and AOX function has been
 397 linked to both abiotic and biotic stress responses (Vanlerberghe, 2013). Only with the explosion of
 398 genome and metagenome sequencing was it discovered that certain bacterial genomes also encode
 399 this protein (Stenmark and Nordlund, 2003), and that *aox*-like genes are abundant in metagenomic
 400 sequences from ocean surface waters (McDonald and Vanlerberghe, 2005). However, early progress
 401 towards understanding the physiological benefit of AOX function in bacteria was limited by the lack
 402 of genetic tools for many of the AOX-encoding organisms. A path to revealing a functional role for
 403 AOX came with the discovery that the genome of *V. fischeri* strain ES114 encoded AOX (Ruby et
 404 al., 2005). A transcriptomic analysis of the *V. fischeri* response to NO revealed that nitric oxide
 405 induces expression of *aox* (Wang et al., 2010a). The connection to NO was further clarified through

characterization of the role of the NO-responsive negative regulator NsrR in regulation of *aox* expression, and identification of the ability of *V. fischeri* AOX to function as an NO-resistant oxidase (Dunn et al., 2010). Despite the known connections between *aox* and NO, and between NO and the early stages of host colonization, no discernible phenotypic difference between the *aox* mutant and wild type in early colonization of the squid host has been observed. Although there is the possibility that AOX does not play a role in bacterial physiology during host colonization, an alternative explanation is that the benefit of AOX expression during colonization does not result in a phenotype dramatic enough to be detected in the short time frame of the experiments (1-3 days). Experiments to test this possibility are in progress and would be consistent with studies above described for luminescence mutants in which colonization phenotypes change over the course of symbiosis and effects are magnified over a multi-week time course.

Studying AOX regulation and function in *V. fischeri* as a model organism will provide a framework for understanding how bacteria in ocean surface waters utilize this respiratory pathway in growth and survival. Work is underway to clarify the physiological benefit of AOX function in *V. fischeri* and other *aox*-containing bacteria, with the ultimate goal of better understanding how bacteria cope with changing conditions in the environment. Studying AOX in the context of the symbiosis has provided insight into the expression and function of this interesting protein, and provides a framework for broad studies of how AOX function influences bacterial physiology in the environment.

Study of AOX followed a reverse-genetic approach, starting with identification of an interesting gene through genome sequencing, and through directed experimental approaches leading to a better understanding of gene function. However, in many cases forward genetic approaches have identified genes whose products are relevant for a specific colonization process. An excellent example is *binK*, which encodes a histidine kinase. Above we described a key role for biofilm formation in the colonization process as regulated by RscS and Syp. In a recent global genetic screen for mutants with an advantage in squid colonization, *binK* was identified as a locus that when disrupted resulted in substantially better colonization of the *V. fischeri* strain (Brooks and Mandel, 2016). Typical means to predict protein function (e.g., homology, neighboring genes) were not helpful, so phenotypes of cells lacking *binK* were examined in culture and in the host and revealed a substantial increase in symbiotic biofilm formation. BinK (biofilm inhibitor kinase) is therefore a negative regulator of biofilm formation and an additional membrane-bound histidine kinase that is critical for proper regulation of the Syp biofilm.

In the case of both AOX and BinK, the depth of the *V. fischeri*-squid system has provided a means to assign function to novel and poorly-understood proteins. A striking number of genes are poorly understood in bacterial genomes, exemplified by the 149 (32 %) of the minimal 473 genes in the JCVI-syn3.0 genome with functions that remain to be discovered (Hutchison et al., 2016). The ability to study biological function in the context of the host thus provides a useful lens through which to identify and characterize genes and their products.

3 Conclusions

The *Vibrio*-squid system has proven to be a valuable study system for identifying principles of microbe-host interactions, continues to serve as a fertile field for discovery, and provides a useful road map for moving from patterns of intriguing phenotypes to discerning the molecular communication between microbe and host that is responsible for those patterns. By integrating approaches in genetics, genomics, molecular biology, imaging, physiology, evolutionary biology, and cell biology, each of the topic areas highlights an integrated and mechanistic view of how symbiotic

Deleted: interaction

partners functionally communicate in a model microbiome. In this manner, the *Vibrio*-squid system provides a durable example for how to move from fascinating observations to molecular understanding of the processes by which very different organisms communicate and establish a productive partnership.

4 Conflict of Interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

5 Author Contributions

MJM and AKD wrote the manuscript.

6 Funding

Research in the authors' laboratories is supported by National Science Foundation awards IOS-1456963 (MJM) and MCB-1050687 (AKD), and National Institutes of Health Awards R35GM119627 (MJM) and R21AI117262 (MJM). The content is solely the responsibility of the authors and does not necessarily represent the official views of the funding agencies.

7 Acknowledgments

We thank Ella Rotman and Denise Tarnowski for comments on the manuscript.

8 Figure Legend

Figure 1. (A) Juvenile *Euprymna scolopes* hatchling, ventral view. White box highlights the ink sac and the light organ. (B) Confocal micrograph of the bilaterally symmetric light organ. Host tissue is counterstained in red and the colonizing bacteria are visible in green. Arrowheads point to the three pores on each side of the organ, into which *V. fischeri* swim into the internal anatomy (ducts, antechamber, bottleneck, and crypts) of the organ. White box highlights one half of the organ, which is shown in cartoon view in the next panel. (C) Current state of knowledge about the temporal and spatial action of key processes discussed in this review, including Syp biofilm formation and aggregation (red), host nitric oxide production (yellow), bacterial motility and chemotaxis toward host chitin oligosaccharides (orange), symbiont TCT release (green), and luminescence (blue). In general the location of the colonizing bacteria are highlighted; e.g., for TCT release the bacteria colonize the crypts and release TCT (indicated), though the effect of this release on the host is apoptosis and regression of the ciliated epithelial appendages (not indicated in this representation). Panels A and B are adapted from (Mandel et al., 2012).
